# Chapter 7

## **Termination Detection**

## 7.1 Introduction

In distributed processing systems, a problem is typically solved in a distributed manner with the cooperation of a number of processes. In such an environment, inferring if a distributed computation has ended is essential so that the results produced by the computation can be used. Also, in some applications, the problem to be solved is divided into many subproblems, and the execution of a subproblem cannot begin until the execution of the previous subproblem is complete. Hence, it is necessary to determine when the execution of a particular subproblem has ended so that the execution of the next subproblem may begin. Therefore, a fundamental problem in distributed systems is to determine if a distributed computation has terminated.

The detection of the termination of a distributed computation is non-trivial since no process has complete knowledge of the global state, and global time does not exist. A distributed computation is considered to be globally terminated if every process is locally terminated and there is no message in transit between any processes. "Locally terminated" state is a state in which a process has finished its computation and will not restart any action unless it receives a message. In the termination detection problem, a particular process (or all of the processes) must infer when the underlying computation has terminated.

When we are interested in inferring when the underlying computation has ended, a termination detection algorithm is used for this purpose. In such situations, there are two distributed computations taking place in the distributed system, namely, the underlying computation and the termination detection algorithm. Messages used in the underlying computation are called basic messages, and messages used for the purpose of termination detection (by a termination detection algorithm) are called control messages.

A termination detection (TD) algorithm must ensure the following:

- 1. Execution of a TD algorithm cannot indefinitely delay the underlying computation; that is, execution of the termination detection algorithm must not freeze the underlying computation.
- 2. The termination detection algorithm must not require addition of new communication channels between processes.

## 7.2 System Model of a Distributed Computation

A distributed computation consists of a fixed set of processes which communicate solely by message passing. All messages are received correctly after an arbitrary but finite delay. Communication is *asynchronous*, i.e., a process never waits for the receiver to be ready before sending a message. Messages sent over the same communication channel may not obey the FIFO ordering.

The distributed computation has the following characteristics:

- 1. At any given time during execution of the distributed computation, a process can be in only one of the two states: *active*, where it is doing local computation and *idle*, where the process has (temporarily) finished the execution of its local computation and will be reactivated only on the receipt of a message from another process. The active and idle states are also called the *busy* and *passive* states, respectively.
- 2. An active process can become idle at any time. This corresponds to the situation where the process has completed its local computation and has processed all received messages.
- 3. An idle process can become active only on the receipt of a message from another process. Thus, an idle process cannot spontaneously become active (except when the distributed computation begins execution).
- 4. Only active processes can send messages. (Since we are not concerned with the initialization problem, we assume that all processes are initially idle and a message arrives from outside the system to start the computation.)
- 5. A message can be received by a process when the process is in either of the two states, i.e., active or idle. On the receipt of a message, an idle process becomes active.
- 6. The sending of a message and the receipt of a message occur as atomic actions.

We restrict to executions in which every process eventually becomes idle, although this property is in general undecidable. If a termination detection algorithm is applied to a distributed computation in which some processes remain in their active states forever, the TD algorithm itself will not terminate.

#### **Definition of Termination Detection**

Let  $p_i(t)$  denote the state (active or idle) of process  $p_i$  at instant t and  $c_{i,j}(t)$  denote the number of messages in transit in the channel at instant t from process  $p_i$  to process  $p_j$ . A distributed computation is said to be terminated at time instant  $t_0$  iff:

$$(\forall i :: p_i(t_0) = idle) \land (\forall i, j :: c_{i,j}(t_0) = 0).$$

## 7.3 Termination Detection Using Distributed Snapshots

The algorithm uses the fact that a consistent snapshot of a distributed system captures stable properties. Termination of a distributed computation is a stable property. Thus, if a consistent snapshot of a distributed computation is taken after the distributed computation has terminated, the snapshot will capture the termination of the computation.

The algorithm assumes that there is a logical bidirectional communication channel between every pair of processes. Communication channels are reliable but non-FIFO. Message delay is arbitrary but finite.

#### 7.3.1 Informal Description

The main idea behind the algorithm is as follows: When a computation terminates, there must exist a unique process which became idle last. When a process goes from active to idle, it issues a request to all other processes to take a local snapshot, and also requests itself to take a local snapshot. When a process receives the request, if it agrees that the requester became idle before itself, it grants the request by taking a local snapshot for the request. A request is said to be *successful* if all processes have taken a local snapshot for it. The requester or any external agent may collect all the local snapshots of a request. If a request is successful, a global snapshot of the request can thus be obtained and the recorded state will indicate termination of the computation, viz., in the recorded snapshot, all the processes are idle and there is no message in transit to any of the processes.

## 7.3.2 Formal Description

The algorithm needs logical time to order the requests. Each process i maintains an  $logical\ clock$  denoted by x, which is initialized to zero at the start of the computation. A process increments its x by one each time it becomes idle. A basic message sent by a process at its logical time x is of the form B(x). A control message that requests processes to take local snapshot issued by process i at its logical time x is of the form R(x, i). Each process synchronizes its logical clock x loosely with the logical clocks x's on other processes in such a way that it is the maximum of clock values ever received or sent in messages. Besides logical clock x, a process maintains a variable x such that when the process is idle, x, x is the maximum of the values x, x on all messages x, x ever received or sent by the process. Logical time is compared as follows: x, x on all messages x, x or x

The algorithm is defined by the following four rules. We use guarded statements to express the conditions and actions. Each process i applies one of the rules whenever it is applicable.

(R1): When process i is active, it may send a basic message to process j at any time by doing send a B(x) to j.

```
(R2): Upon receiving a B(x'), process i does let x:=x'+I; if (i \text{ is idle}) \to \text{go active}.

(R3): When process i goes idle, it does let x:=x+I; let k:=i; send message R(x, k) to all other processes; take a local snapshot for the request by R(x, k).

(R4): Upon receiving message R(x', k'), process i does [((x', k') > (x,k)) \land (i \text{ is idle}) \to \text{let } (x,k):=(x', k'); take a local snapshot for the request by R(x', k'); ((x', k') \le (x,k)) \land (i \text{ is idle}) \to \text{do nothing}; (i \text{ is active}) \to \text{let } x:=\max(x', x)].
```

#### 7.3.3 Discussion

As per Rule R1, when a process sends a basic message to any other process, it sends its logical clock value in the message. From Rule R2, when a process receives a basic message, it updates its logical clock based on the clock value contained in the message. Rule 3 states that when a process becomes idle, it updates its local clock, sends a request for snapshot R(x, k) to every other process, and takes a local snapshot for this request.

Rule R4 is the most interesting. On the receipt of a message R(x', k'), the process takes a local snapshot if it is idle and (x', k') > (x, k), i.e., timing in the message is later than the local time at the process, implying that the sender of R(x', k') terminated after this process. In this case, it is likely that the sender is the last process to terminate and thus, the receiving process takes a snapshot for it. Because of this action, every process will eventually take a local snapshot for the last request when the computation has terminated, that is, the request by the latest process to terminate will become successful.

In the second case,  $(x', k') \le (x,k)$ , implying that the sender of R(x', k') terminated before this process, hence, the sender of R(x', k') can not be the last process to terminate. Thus, the receiving process does not take a snapshot for it. In the third case, the receiving process has not even terminated. Hence, the sender of R(x', k') can not be the last process to terminate and no snapshot is taken.

The last process to terminate will have the largest clock value. Therefore, every process will take a snapshot for it, however, it will not take a snapshot for any other process.

## 7.4 Termination Detection by Weight Throwing

In termination detection by weight throwing, a process called *controlling agent*<sup>1</sup> monitors the computation. A communication channel exists between each of the processes and the controlling agent and also between every pair of processes.

#### **Basic Idea**

Initially, all processes are in the idle state. The weight at each process is zero and the weight at the controlling agent is 1. The computation starts when the controlling agent sends a basic message to one of the processes. The process becomes active and the computation starts. A non-zero weight  $W(0 < W \le 1)$  is assigned to each process in the active state and to each message in transit in the following manner: When a process sends a message, it sends a part of its weight in the message. When a process receives a message, it add the weight received in the message to its weight. Thus, the sum of weights on all the processes and on all the messages in trasit is always 1. When a process becomes passive, it sends its weight to the controlling agent in a control message, which the controlling agent adds to its weight. The controlling agent concludes termination if its weight becomes 1.

#### **Notations**

The weight on the controlling agent and a process is in general represented by W.

B(DW) - a basic message B sent as a part of the computation, where DW is the weight assigned to it.

C(DW) - a control message C sent from a process to the controlling agent where DW is the weight assigned to it.

## 7.4.1 Formal Description

The algorithm is defined by the following four rules:

**Rule 1:** The controlling agent or an active process may send a basic message to one of the processes, say P, by splitting its weight W into W1 and W2 such that W1+W2=W, W1>0 and W2>0. It then assigns its weight W:=W1 and sends a basic message B(DW:=W2) to P.

**Rule 2:** On the receipt of the message B(DW), process P adds DW to its weight W (W:=W+DW). If the receiving process is in the idle state, it becomes active.

<sup>&</sup>lt;sup>1</sup>The controlling agent can be one of the processes in the computation.

**Rule 3:** A process switches from the active state to the idle state at any time by sending a control message C(DW:=W) to the controlling agent and making its weight W:=0.

**Rule 4:** On the receipt of a message C(DW), the controlling agent adds DW to its weight (W:=W+DW). If W=1, then it concludes that the computation has terminated.

#### 7.4.2 Correctness of the Algorithm

To prove the correctness of the algorithm, the following sets are defined:

A: set of weights on all active processes

B: set of weights on all basic messages in transit

C: set of weights on all control messages in transit

W<sub>c</sub>: weight on the controlling agent.

Two invariants  $I_1$  and  $I_2$  are defined for the algorithm:

$$I_1: \mathbf{W}_c + \sum_{W \in (A \cup B \cup C)} \mathbf{W} = 1$$
$$I_2: \forall \mathbf{W} \in (\mathbf{A} \cup B \cup \mathbf{C}), \mathbf{W} > 0$$

Invariant  $I_1$  states that sum of weights at the controlling process, at all active processes, on all basic messages in transit, and on all control messages in transit is always equal to 1. Invariant  $I_2$  states that weight at each active process, on each basic message in transit, and on each control message in transit is non-zero.

Hence,

$$\begin{aligned} \mathbf{W}_c &= 1 \\ &: \sum_{W \in (A \cup B \cup C)} \mathbf{W} = 0 \text{ (by } I_1) \\ &: (A \cup B \cup C) = \phi \text{ (by } I_2) \\ &: (A \cup B) = \phi. \end{aligned}$$

Note that  $(A \cup B) = \phi$  implies the computation has terminated. Therefore, the algorithm never detects a false termination.

Further,

$$(A \cup B) = \phi$$
  
:  $\mathbf{W}_c + \sum_{W \in C} \mathbf{W} = 1 \text{ (by } I_1)$ 

Since the message delay is finite, after the computation has terminated, eventually  $W_c=1$ . Thus, the algorithm detects a termination in finite time.

## 7.5 A Spanning-Tree-Based Termination Detection Algorithm

The algorithm assumes there are N processes  $P_i$ ,  $0 \le i \le N$ , which are modeled as the nodes i,  $0 \le i \le N$ , of a fixed connected undirected graph. The edges of the graph represent the communication channels, through which a process sends messages to neighboring processes in the graph. The algorithm uses a fixed spanning tree of the graph with process  $P_0$  at its root which is responsible for termination detection. Process  $P_0$  communicates with other processes to determine their states and the messages used for this purpose are called signals. All leaf nodes report to their parents, if they have terminated. A parent node will similarly report to its parent when it has completed processing and all of its immediate children have terminated, and so on. The root concludes that termination has occurred, if it has terminated and all of its immediate children have also terminated.

The termination detection algorithm generates two waves of signals moving inward and outward through the spanning tree. Initially, a contracting wave of signals, called *tokens*, moves inward from leaves to the root. If this token wave reaches the root without discovering that termination has occurred, the root initiates a second outward wave of *repeat* signals. As this repeat wave reaches leaves, the token wave gradually forms and starts moving inward again. This sequence of events is repeated until the termination is detected.

#### 7.5.1 Definitions

- 1. Tokens: A contracting wave of signals that move inward from the leaves to the root.
- 2. Repeat signal: If a token wave fails to detect termination, node P0 initiates another round of termination detection by sending a signal called Repeat, to the leaves.
- 3. The nodes which have one or more tokens at any instant form a set S.
- 4. A node j is said to be outside of set S if j does not belong to S and the path (in the tree) from the root to j contains an element of S. Every path from the root to a leaf may not contain a node of S.
- 5. Note that all nodes outside S are idle. This is because, any node that terminates, transmits a token to its parent. When a node transmits the token, it goes out of the set S.

We first give a simple algorithm for termination detection and discuss a problem associated with it. Then we provide the correct algorithm.

## 7.5.2 A Simple Algorithm

Initially, each leaf process is given a token. Each leaf process, after it has terminated sends its token to its parent. When a parent process terminates and after it has received a token from each of its children, it sends a token to its parent. This way, each process indicates to its parent process that the subtree below it has become idle. In a similar manner, the tokens get propagated to the

root. The root of the tree concludes that termination has occurred, after it has become idle and has received a token from each of its children.

#### A Problem with the algorithm

This simple algorithm fails under some circumstances. After a process has sent its token to its parent, it should remain idle. However, this is not true. The problem arises when a process after it has sent a token to its parent, receives a message from some other process. Note that this message could cause the process (that has already sent a token to its parent) to again become active. Hence the simple algorithm fails since the process that indicated to its parent that it has become idle, is now active because of the message it received from an active process. Hence, the root node just because it received a token from a child, can't conclude that all processes in the child's subtree have terminated. The algorithm has to be reworked to accommodate such message-passing scenarios.

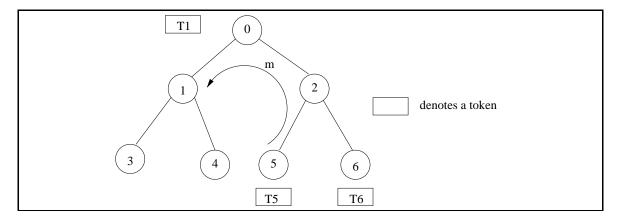

Figure 7.1: An Example of the Problem.

The problem is explained with the example shown in Figure 7.1. Assume that process 1 has sent its token (T1) to its parent, namely, process 0. On receiving the token, process 0 concludes that process 1 and its children have terminated. Process 0 if it is idle, can conclude that termination has occurred, whenever it receives a token from process 2. But now assume that just before process 5 terminates, it sends a message m to process 1. On the reception of this message, process 1 becomes active again. Thus, the information that process 0 has about process 1 (that it is idle) becomes void. Therefore, this simple algorithm does not work.

## 7.5.3 The Correct Algorithm

We now present the correct algorithm that works even when messages such as above are present. The main idea is to color the processes and tokens and change the color when messages such as above are involved.

#### The Basic Idea

In order to enable the root node to know that a node in its children's subtree, that was assumed to be terminated, has become active due to a message, a coloring scheme for tokens and nodes is used. The root can determine that an idle process has been activated by a message, based on the color of the token it receives from its children. All tokens are initialized to white color. If a process had sent a message to some other process, it sends a black token to its parent on termination; otherwise, it sends a white token on termination. Hence, the parent process on getting the black token knows that its child had sent a message to some other process. The parent, when sending its token (on terminating) to its parent, sends a black token only if it received a black token from one of its children. This way, the parent's parent knows that one of the processes in its child's subtree had sent a message to some other process. This gets propagated and finally the root node knows that message-passing was involved when it receives a black token from one of its children. In this case, the root asks all nodes in the system to restart the termination detection. For this, the root sends a repeat signal to all other process. After receiving the repeat signal, all leaves will restart the termination detection algorithm.

## **The Algorithm Description**

The algorithm works as follows:

- 1. Initially, each leaf process is provided with a token. The set S is used for book-keeping to know which processes have the token. Hence S will be the set of all leaves in the tree.
- 2. Initially, all processes and tokens are colored white. As explained above, coloring helps the root know if a message-passing was involved in one of the subtrees.
- 3. When a leaf node terminates, it sends the token it holds to its parent process.
- 4. A parent process will collect the token sent by each of its children. After it has received a token from all of its children and after it has terminated, the parent process sends a token to its parent.
- 5. A process turns black when it sends a message to some other process. This coloring scheme helps a process remember that it has sent a message. When a process terminates, if its color is black, it sends a black token to its parent.
- 6. A black process turns back to white, after it has sent a black token to its parent.
- 7. A parent process holding a black token (from one of its children), sends only a black token to its parent, to indicate that a message-passing was involved in its subtree.
- 8. Tokens are propagated to the root in this fashion. The root, upon receiving a black token, will know that a process in the tree had sent a message to some other process. Hence, it restarts the algorithm by sending a Repeat signal to all its children.

- 9. Each child of the root propagates the Repeat signal to each of its children and so on, until the signal reaches the leaves.
- 10. The leaf nodes restart the algorithm on receiving the Repeat signal.
- 11. The root concludes that termination has occurred, if
  - (a) it is white,
  - (b) it is idle, and
  - (c) it received a white token from each of its children.

## 7.5.4 An Example

We now present an example to illustrate the working of the algorithm.

1. Initially, all nodes 0 to 6 are colored white (Figure 7.2). Leaf nodes 3, 4, 5 and 6 are each given a token. Node 3 has token T3, node 4 has token T4, node 5 has token T5, and node 6 has token T6. Hence, S is {3, 4, 5, 6}.

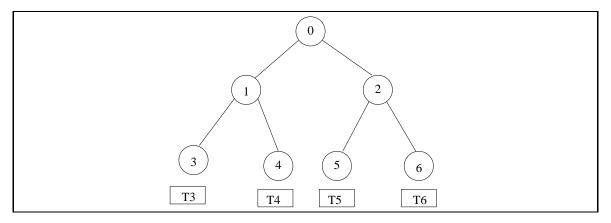

Figure 7.2: All leaf nodes have tokens.  $S=\{3,4,5,6\}$ .

- 2. When node 3 terminates, it transmits T3 to node 1. Now S changes to 1, 4, 5, 6. When node 4 terminates, it transmits T4 to node 1 (Figure 7.3). Hence, S changes to {1, 5, 6}.
- 3. Node 1 has received a token from each of its children and when it terminates, it transmits a token T1 to its parent (Figure 7.4). S changes to  $\{0, 5, 6\}$ .
- 4. After this, suppose node 5 sends a message to node 1, causing node 1 to again become active (Figure 7.5). Since node 5 had already sent a token to its parent node 0 (thereby, making node 0 assume that node 5 had terminated), the new message makes the system inconsistent as far as termination detection is concerned. To deal with this, the algorithm executes the following steps.

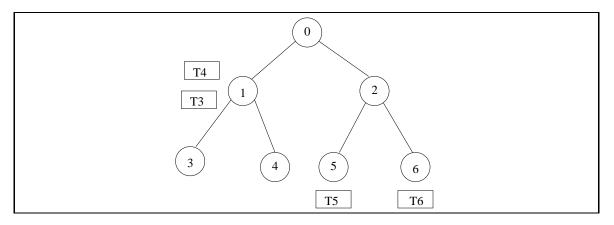

Figure 7.3: Nodes 3 and 4 become idle.  $S=\{1,5,6\}$ .

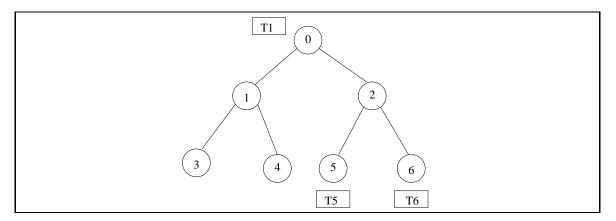

Figure 7.4: Node 1 becomes idle.  $S=\{0,5,6\}$ .

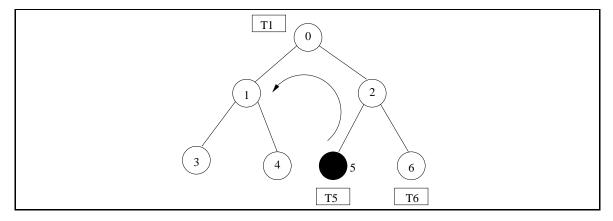

Figure 7.5: Node 5 sends a message to node 1.

- 5. Node 5 is colored black, since it sent a message to node 1.
- 6. When node 5 terminates, it sends a black token T5 to node 2. So, S changes to  $\{0, 2, 6\}$ . After node 5 sends its token, it is colored white (Figure 7.6). When Node 6 terminates, it sends the white token T6 to node 2. Hence, S changes to  $\{0, 2\}$ .

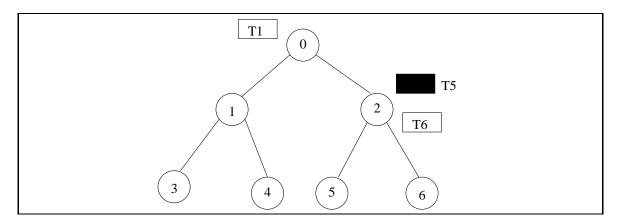

Figure 7.6: Nodes 5 and 6 become idle.  $S=\{0,2\}$ .

7. When node 2 terminates, it sends a black token T2 to node 0, since it holds a black token T5 from node 5 (Figure 7.7).

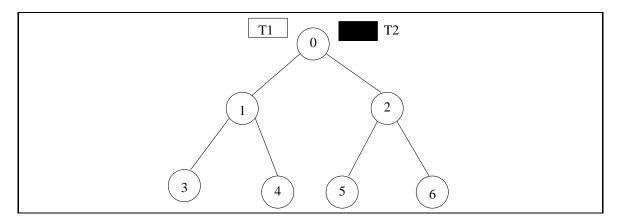

Figure 7.7: Node 2 becomes idle.  $S=\{0\}$ . Node 0 initiates a repeat signal.

- 8. Since node 0 has received a black token T2 from node 2, it knows that there was a message sent by one or more of its children in the tree and hence it sends a repeat signal to each of its children.
- 9. The repeat signal is propagated to the leaf nodes and the algorithm is repeated. Node 0 concludes that termination has occurred, if it is white, it is idle, and it has received a white token from each of its children

#### 7.5.5 Performance

The best case message complexity of the algorithm is O(N), where N is the number of processes in the computation. The best case occurs when all nodes send all computation messages in the first round. Therefore, the algorithm executes only twice and the message complexity depends only on the number of nodes.

However, the worst case complexity of the algorithm is O(N\*M), where M is the number of computation messages exchanged. The worst case occurs when only computation message is exchanged every time the algorithm is executed. This causes the root to restart termination detection as many times as there are no computation messages. Hence, the worst case complexity is O(N\*M).

## 7.6 Message-Optimal Termination Detection

Now we discuss a message optimal termination detection algorithm by Chandrasekaran and Venkatesan [2]. The network is represented by a graph G = (V, E), where V is the set of nodes, and  $E \subseteq V \times V$  is the set of edges or communication links. The communication links are bidirectional and exhibit FIFO property. The processors and communication links incur arbitrary but finite delays in executing their functions. The algorithm assumes the existence of a leader and a spanning tree in the network. If a leader is not available, the minimum spanning tree algorithm of Gallager et al. can be used to elect a leader and find a spanning tree using  $O(|E| + |V| \log |V|)$  messages.

#### 7.6.1 The Main Idea

Let us consider the following method for termination detection due to Topor: The root of the tree initiates one phase of termination detection by turning white. An interior node, on receiving a white token from its parent, turns white and transmits a white token to all of its children. Eventually each leaf receives a white token and turns white. When a leaf node becomes idle, it transmits a token to its parent and the token has the same color as that of the leaf node. An interior node waits for a token from each of its children. It also waits until it becomes idle. It then sends a white token to its parent if its color is white and it received a white token from each of its children. Finally, the root node infers the termination of the underlying computation if it receives a white token from each child, its color is white, and it is idle.

This simple algorithm is inefficient in terms of message complexity due to the following reasons: Consider the scenario shown in Figure 7.8, where node p sends a message m to node q. Before node q received the message m, it had sent a white token to its parent (because it was idle and it had received a white token from each of its children). In this situation, node p can not send a white token to its parent until node q becomes idle. To insure this, in Topor's algorithm, node p changes its color to black and sends a black token to its parent so that termination detection is performed once again. Thus, every message of the underlying computation can potentially cause

the execution of one more round of the termination detection algorithm, resulting in significant message traffic.

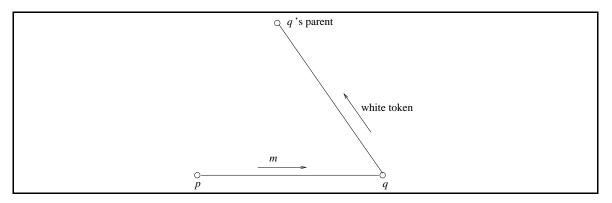

Figure 7.8: Node p sends a message m to node q that has already sent a white token to its parent.

The main idea behind the message-optimal algorithm is as follows: When a node p sends a message m to node q, p should wait until q becomes idle and only after that, p should send a white token to its parent. This rule ensures that if an idle node q is restarted by a message m from from a node p, then the sender p waits till q terminates before p can send a white token to its parent. To achieve this, when node q terminates, it sends an acknowledgement (a control message) to node p informing node p that the set of actions triggered by message m has been completed and that node p can send a white token to its parent. However, note that node q, after being woken up by message p from node p, may wake up another idle node p, which in turn may wake up other nodes. Therefore, node p should not send an acknowledgement to p until it receives acknowledgement messages for all of the messages it sent after it received message p from node p. This restriction also applies to node p and other nodes. Clearly, both the sender and the receiver keep track of each message, and a node sends a white token to its parent only after it receives an acknowledgement for every message it sent and it has received a white token from each of its children.

## 7.6.2 Formal Description of the Algorithm

Initially, all nodes in the network are in state NDT (not detecting termination) and all links are uncolored. For termination detection, the root node changes its state to DT (detecting termination) and sends a warning message on each of its outgoing edges. When a node p receives a warning message from its neighbor, say q, it colors<sup>2</sup> the incoming link (q, p) and if it is in state NTD, it changes its state to DT, colors each of its outgoing edges, and sends a warning message on each of its outgoing edges.

When a node p in state DT sends a basic message to its neighbor q, it keeps track of this information by pushing the entry TO(q) on its local stack.

When a node x receives a basic message from node y on the link (y, x) that is colored by x, node x knows that the sender node y will need an acknowledgement for this message from it. The

<sup>&</sup>lt;sup>2</sup>All links are uncolored or colored. The shade of the color does not matter.

receiver node x keeps track of this information by pushing the entry FROM(y) on its local stack. Procedure receive\_message is given below:

```
Procedure receive_message(y: neighbor);
```

(\* performed when a node x receives a message from its neighbor y on the link (y,x) that was colored by x \*)

#### begin

```
receive message from y on the link (y,x) if (link(y,x) has been colored by x) then push FROM(y) on the stack
```

#### end:

Eventually, every node in the network will be in the state DT as the network is connected. Note that both sender and receiver keep track of every message in the system.

When a node p becomes idle, it calls procedure stack\_cleanup which is defined below. Procedure stack\_cleanup examines its stack from the top, and for every entry of the form FROM(q), it deletes the entry and sends the  $remove\_entry$  message to node q. Node p repeats this until it encounters an entry of the form TO(x) on the stack. The idea behind this step is to inform those nodes that sent a message to p that the actions triggered by their messages to p are complete.

```
Procedure stack_cleanup; begin  
while (top entry on stack is not of the form "TO()") do begin  
pop the entry on the top of the stack; let the entry be FROM(q); send a remove_entry message to q end
```

#### end:

When a node x receives a  $remove\_entry$  message from its neighbour y, node x infers that the operations triggered by its last message to y have been completed and hence it no longer needs to keep track of this information. Node x on receipt of the control message  $remove\_entry$  from node y, examines its stack from the top and deletes the first entry of the form TO(y) from the stack. If node x is idle, it also performs the  $stack\_cleanup$  operation. The procedure  $receive\_remove\_entry$  is defined as follows:

```
Procedure receive_remove_entry(y: neighbor); (* performed when a node x receives a remove_entry message from its neighbor y *)
```

#### begin

scan the stack and delete the first entry of the form TO(y); if idle then

stack\_cleanup

#### end;

A node sends a terminate message to its parent when it satisfies all the following conditions:

- 1. It is idle.
- 2. Each of its incoming links is colored (it has received a warning message on each of its incoming links).
- 3. Its stack is empty.
- 4. It has received a *terminate* message from each of its children (this rule does not apply to leaf nodes).

When the root node satisfies all of the above conditions, it concludes that the underlying computation has terminated.

#### 7.6.3 Performance

We analyze the number of control messages used by the algorithm in the worst case. Each node in the network sends one warning message on each outgoing link. Thus, each link carries two warning messages, one in each direction. Since there are |E| links, the total number of warning messages generated by the algorithm is 2\*|E|. For every message generated by the underlying computation (after the start of the termination detection algorithm), exactly one *remove\_message* is sent on the network. If M is the number of messages sent by the underlying computation, then at most M *remove\_entry* messages are used. Finally, each node sends exactly one *terminate* message to its parent (on the tree edge) and since there are only |V| nodes and |V|-1 tree edges, only |V|-1 *terminate* messages are sent. Hence, the total number of messages generated by the algorithm is 2\*|E|+|V|-1+M. Thus, the message complexity of the algorithm is O(|E|+M) as |E|>|V|-1 for any connected network. The algorithm is asymptotically optimal in the number of messages.

# 7.7 Termination Detection in a Very General Distributed Computing Model

So far we assumed that the reception of a single message is enough to activate a passive process. Now we consider a general model of distributed computing where a passive process does not necessarily become active on the receipt of a message. Instead, the condition of activation of a passive process is more general and a passive process requires a set of messages to become active.

This requirement is expressed by an *activation condition* defined over the set  $DS_i$  of processes from which a passive process  $P_i$  is expecting messages. The set  $DS_i$  associated with a passive process  $P_i$  is called the *dependent set* of  $P_i$ . A passive process becomes active only when its activation condition is fulfilled.

#### 7.7.1 Model Definition and Assumptions

The distributed computation consists of a finite set P of processes  $P_i$ , i=1, ...,n, interconnected by unidirectional communication channels. Communication channels are reliable, but they do not obey FIFO property. Message transfer delay is finite but unpredictable.

A passive process that has terminated its computation by executing for example an end or stop statement is said to be individually terminated; its dependent set is empty and therefore, it can never be activated.

#### AND, OR, and ANO-OR Models

There are several request models, such as AND, OR, AND-OR models. In the AND model, a passive process  $P_i$  can be activated only after a message from every process belonging to  $DS_i$  has arrived. In the OR model, a passive process  $P_i$  can be activated when a message from any process belonging to  $DS_i$  has arrived. In the AND-OR model, the requirement of a passive process  $P_i$  is defined by a set  $P_i$  of sets  $DS_i^1, DS_i^2, ...DS_i^q$ , such that for all  $P_i$  is  $P_i = P_i$  is  $P_i = P_i$  is  $P_i = P_i$  is  $P_i = P_i$ . Process  $P_i$  waits for messages from all processes belonging to  $P_i$  or for messages from all  $P_i$  or for messages from all  $P_i$  or for messages from all  $P_i$  or for  $P_i$  or  $P_i$  or for  $P_i$  or  $P_i$  or  $P_i$ 

#### The k out of n Model

In the k out of n model, the requirement of a passive process  $P_i$  is defined by the set  $DS_i$  and an integer  $k_i$ ,  $1 \le k_i \le |DS_i| = n_i$  and process  $P_i$  becomes active when it has received messages from  $k_i$  distinct processes in  $DS_i$ . Note that a more general k out of n model can be constructed as disjunctions of several k out of n requests.

#### **Predicate fulfilled**

To abstract the activation condition of a passive process  $P_i$ , a predicate  $fulfilled_i(A)$  is introduced, where A is a subset of P. Predicate  $fulfilled_i(A)$  is true if and only if messages arrived (and not yet consumed) from all processes belonging to set A are sufficient to activate process  $P_i$ .

#### 7.7.2 Notations

The following notations will be used to define termination of a distributed computation:

•  $passive_i$ : true iff  $P_i$  is passive

- empty(j, i): true iff all messages sent by  $P_j$  to  $P_i$  have arrived at  $P_i$ ; the messages not yet consumed by  $P_i$  are in its local buffer.
- $arr_i(j)$ : true iff a message from  $P_j$  to  $P_i$  has arrived at  $P_i$  and has not yet been consumed by  $P_i$ .
- $ARR_i = \{ \text{processes } P_j \text{ such that } arr_i(j) \}.$
- $NE_i = \{\text{processes } P_j \text{ such that } \neg \text{ empty}(j, i)\}.$

#### 7.7.3 Termination Definitions

Two different types of terminations are defined, dynamic termination and static termination:

• <u>Dynamic termination</u>: The set of processes *P* is said to be dynamically terminated at some instant if and only if the predicate *Dterm* is true at that moment where:

```
Dterm \equiv \forall P_i \in P: passive_i \land \neg fulfilled_i(ARR_i \cup NE_i).
```

Dynamic termination means that no more activity is possible from processes, though messages of the underlying computation can still be in transit. This definition is useful in "early" detection of termination as it allows concluding a computation has terminated even if some of its messages have not yet arrived.

Note that dynamic termination is a stable property because once Dterm is true, it remains true.

• <u>Static termination:</u> The set of processes *P* is said to be statically terminated at some instant if and only if the predicate *Sterm* is true at that moment where:

$$Sterm \equiv \forall P_i \in P: passive_i \land (NE_i = \emptyset) \land \neg fulfilled_i(ARR_i)$$

Static termination means all channels are empty and none of the processes can be activated. Thus, static termination is focused on the state of both channels and processes. When compared to *Dterm*, the predicate *Sterm* corresponds to "late" detection as, additionally, all channels must be empty.

## 7.7.4 A Static Termination Detection Algorithm

## **Informal Description**

A control process  $C_i$ , called *controller*, is associated with each application process  $P_i$ . Its role is to observe the behavior of process  $P_i$  and to cooperate with other controllers  $C_j$  to detect occurrence

of the predicate *Sterm*. In order to detect static termination, a controller, say  $C_a$ , initiates detection by sending a control message *query* to all controllers (including itself). A controller  $C_i$  responds with a message  $reply(ld_i)$ , where  $ld_i$  is a Boolean value.  $C_a$  combines all the Boolean values received in reply messages to compute  $td:=\bigwedge_{1\leq i\leq n}ld_i$ . If td is true,  $C_a$  concludes that termination

has occurred. Otherwise, it sends new *query* messages. The basic sequence of sending of *query* messages followed by the reception of associated *reply* messages is called a *wave*.

The core of the algorithm is the way a controller  $C_i$  computes the value  $ld_i$  sent back in a *reply* message. To ensure safety, the values  $ld_1,...ld_n$  must be such that:

$$\bigwedge_{1 \leq i \leq n} ld_i : Sterm \\ : \forall P_i \in \mathbf{P}: passive_i \land (NE_i = \emptyset) \land \neg fulfilled_i(ARR_i).$$

A controller  $C_i$  delays a response to a *query* as long as the following locally evaluable predicate is false:  $passive_i \wedge (notack_i = 0) \wedge \neg fulfilled_i(ARR_i)$ . When this predicate is false, the static termination cannot be guaranteed.

For correctness, the values reported by a wave must not miss activity of processes "in the back" of the wave. This is achieved in the following manner: each controller  $C_i$  maintains a Boolean variable  $cp_i$  (initialized to true iff  $P_i$  is initially passive) in the following way:

- When  $P_i$  becomes active,  $cp_i$  is set to false.
- When  $C_i$  sends a reply message to  $C_a$ , it sends the current value of  $cp_i$  with this message, and then sets  $cp_i$  to true.

Thus, if a reply message carries value true from  $C_i$  to  $C_a$ , it means that  $P_i$  has been continuously passive since the previous wave, and the messages arrived and not yet consumed are not sufficient to activate  $P_i$ , and all output channels of  $P_i$  are empty.

## **Formal Description**

The algorithm for static termination detection is as follows. By a *message*, we mean any message of the underlying computation; *queries* and *replies* are called *control* messages.

```
S1: When P_i sends a message to P_j notack_i := notack_i + 1 S2: When a message from P_j arrives to P_i send ack to C_j
```

```
S4: When P_i becomes active cp_i := false
```

(\* A passive process can only become active when its activation condition is true; this activation is under the control of the underlying operating system, and the termination detection algorithm only observes it. \*)

```
S5: When C_i receives query from C_{\alpha} (* Executed only by C_{\alpha} *)

Wait until

((passive_i \land (notack_i = \emptyset) ) \neg fulfilled_i (ARR_i));
ld_i := cp_i;
cp_i := true;
send \ reply(ld_i) \ to \ C_{\alpha}

S6: When controller C_a decides to detect static termination repeat send query to all C_i;
td := \bigwedge_{1 \le i \le n} ld_i;
until \ td;
claim \ static \ termination
```

#### **Performance**

The efficiency of this algorithm depends on the implementation of waves. Two waves are in general necessary to detect static termination. A wave needs two types of messages: n queries and n replies, each carrying one bit. Thus, 4n control messages of two distinct types carrying at most one bit each are used to detect the termination once it has occurred. If waves are supported by a ring, this complexity reduces to 2n. The detection delay is equal to duration of two sequential wave executions.

## 7.7.5 A Dynamic Termination Detection Algorithm

Recall that a dynamic termination can occur before all messages of the computation have arrived. Thus, termination of the computation can be detected sooner than in static termination.

### **Informal Description**

Let  $C_{\alpha}$  denote the controller that launches the waves. In addition to  $cp_i$ , each controller  $C_i$  has the following two vector variables, denoted as  $s_i$  and  $r_i$ , that count messages, respectively, sent to and received from every other process.

- $s_i[j]$  denotes the number of messages sent by  $P_i$  to  $P_j$ .
- $r_i[j]$  denotes the number of messages received by  $P_i$  from  $P_j$ .

Let S denote an  $n \times n$  matrix of counters used by  $C_{\alpha}$ ; entry S[i, j] represents  $C_{\alpha}$ 's knowledge about the number of messages sent by  $P_i$  to  $P_j$ .

First,  $C_a$  sends to each  $C_i$  a query message containing the vector (S[1,i],...,S[n,i]), denoted by S[.,i]. Upon receiving this query message,  $C_i$  computes the set  $ANE_i$  of its non-empty channels. This is an approximate knowledge but is sufficient to ensure correctness. Then  $C_i$  computes  $ld_i$  which is true if and only if  $P_i$  has been continuously passive since the previous wave and its requirement cannot be fulfilled by all the messages arrived and not yet consumed  $(ARR_i)$  and all messages potentially in its input channels  $(ANE_i)$ .  $C_i$  sends to  $C_\alpha$  a reply message carrying the values  $ld_i$  and vector  $s_i$ . Vector  $s_i$  is used by  $C_\alpha$  to update row S[i,.] and thus gain more accurate knowledge. If  $\bigwedge_{1 \le i \le n} ld_i$  evaluates to true,  $C_a$  claims dynamic termination of the underlying computation. Otherwise,  $C_\alpha$  launches a new wave by sending query messages.

Vector variables  $s_i$  and  $r_i$  allow  $C_{\alpha}$  to update its (approximate) global knowledge about messages sent by each  $P_i$  to each  $P_j$  and get an approximate knowledge of the set of non-empty input channels.

## **Formal Description**

All controllers  $C_i$  execute statements S1 to S4. Only the initiator  $C_{\alpha}$  executes S5. Local variables  $s_i$ ,  $r_i$  and S are initialized to 0.

S1: When 
$$P_i$$
 sends a message to  $P_j$   
 $s_i[j] := s_i[j] + 1$ 

S2: When a message from  $P_j$  arrives at  $P_i$ 

$$r_i[j] := r_i[j] + 1$$

S3: When  $P_i$  becomes active

$$cp_i := false$$

S4: When 
$$C_i$$
 receives query(VC[1.. $n$ ]) from  $C_{\alpha}$   
(\* VC[1.. $n$ ] = S[1.. $n$ , $i$ ] is the i-th column of S \*)  
 $ANE_i := \{P_j : VC[j] > r_i[j]\};$ 

```
cp_i \coloneqq (state_i = \mathsf{passive}); send \mathsf{reply}(ld_i,s_i) to C_\alpha S5: When controller C_\alpha decides to detect dynamic termination repeat for each C_i send query(S[1..n,i]) to C_i; (* the i-th column of S is sent to C_i *) \mathsf{receive} \ \mathsf{reply}(ld_i,s_i) \ \mathsf{from} \ \mathsf{all} \ C_i; \forall \ i \in [1..n] : S[i,.] \coloneqq s_i; \mathsf{td} \coloneqq \bigwedge_{1 \le i \le n} ld_i until \mathsf{td}; claim \ dynamic \ termination
```

 $ld_i := cp_i \land \neg fulfilled_i(ARR_i \cup NE_i);$ 

#### **Performance**

The dynamic termination detection algorithm needs two waves after dynamic termination has occurred to detect it. Thus, its message complexity is 4n which is lower than the static termination detection algorithm since no acknowledgements are necessary. However, messages are composed of n monotonically increasing counters. As waves are sequential, query (and reply) messages between  $C_{\alpha}$  and each  $C_i$  are received and processed in their sending order; this FIFO property can be used in conjunction with the Singhal-Kshemkalyani's differential technique to decrease the size of control messages. The detection delay is two waves but is shorter than the delay of the static termination algorithm as acknowledgements are not used.

## 7.8 Termination Detection in the Atomic Computation Model

Mattern [12] developed several algorithm for termination detection in the atomic computation model.

## **Assumptions**

- Processes communicate solely by messages. Messages are received correctly after an arbitrary but finite delay. Messages sent over the same communication channel may not obey the FIFO rule.
- 2. A *time cut* is a line crossing all process lines. A time line can be a straight vertical line or a zigzag line, crossing all process lines. Time cut of a distributed computation is a set of actions characterized by a fact that whenever an action of a process belongs to that set, all previous actions of the same process also belongs to the set.

3. We assume that all atomic actions are totally globally ordered i.e., no two actions occur at the same time instant.

#### 7.8.1 The Atomic Model of Execution

In the *atomic model* of the distributed computation, a process may at any time take any message from one of its incoming communication channels, immediately change its internal state and at the same instant send out zero or more messages. All local actions at a process are performed in zero time. Thus, consideration of process states is eliminated when performing termination detection.

In the atomic model, a distributed computation has terminated at time instant t if at this instant all communications channels are empty. This is because execution of an internal action at a process is instantaneous.

A dedicated process,  $P_1$ , the initiator, determines if the distributed computation has terminated. The initiator  $P_1$  starts termination detection by sending control messages directly or indirectly to all other processes. Let us assume that processes  $P_1,...,P_n$  are ordered in sequence of the arrival of the control message.

### 7.8.2 A Naive Counting Method

To find out if there are any messages in transit, an obvious solution is to let every process *count* the number of basic messages sent and received. We denote the total number of basic messages  $P_i$  has sent at (global) time instant t by  $s_i(t)$ , and the number of messages received by  $r_i(t)$ . The values of the two local counters are communicated to the initiator upon request. Having directly or indirectly received these values from all processes, the initiator can accumulate the counters. Figure 7.9 shows an example, where the time instants at which the processes receive the control messages and communicate the values of their counters to the initiator are symbolized by striped dots. These are connected by a line representing a "control wave", which induces a time cut.

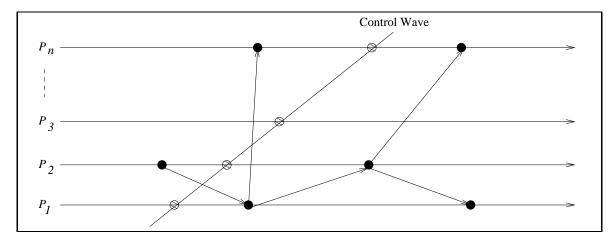

Figure 7.9: An example showing a control wave with a backward communication.

If the accumulated values at the initiator indicate that the sum of all the messages received by

all processes is the same as the sum of all messages sent by all processes, it may give an impression that all the messages sent have been received, i.e., there is no message in transit.

Unfortunately because of the time delay of the control wave, this simple method is not correct. The example in Figure 7.9 shows that the counters can become corrupted by messages "from the future", crossing from the right side of the control wave to its left.

The accumulated result indicates that one message was sent and one received although the computation has not terminated. This misleading result is caused by the fact that the time cut is inconsistent. A time cut is considered to be inconsistent, if when the diagonal line representing it is made vertical, by compressing or expanding the local time scales, a message crosses the control wave backwards.

However, this naive method for termination detection works if the time cut representing the control wave is consistent.

Various strategies can be applied to correct the deficiencies of the naive counting method:

- If the time cut is inconsistent, restart the algorithm later.
- Design techniques that will only provide consistent time cuts.
- Do not lump the count of all messages sent and all messages received. Instead, relate the messages sent and received between pairs of processes.
- Use techniques like freezing the underlying computation.

#### 7.8.3 The Four Counter Method

A very simple solution consists of counting twice using the naive counting method and comparing the results. After the initiator has received the response from the last process and accumulated the values of the counters R\* and S\* (where R\*:=  $\sum_{\forall i} r_i(t_i)$  and S\*:=  $\sum_{\forall i} s_i(t_i)$ ), it starts a second control wave (see Figure 7.10), resulting in values R'\* and S'\*. The system is terminated, if values of the four counters are equal, i.e., R\* = S\* = R'\* = S'\*. In fact, a slightly stronger result exists: If R\* = S'\*, then the system had terminated at the end of the first wave ( $t_2$  in Figure 7.10).

Let t2 denote the time instant at which the first wave is finished, and  $t3 \ge t2$  denote the starting time of the second wave (see Figure 7.10).

- 1. Local message counters are monotonic,  $t \leq t'$  implies  $s_i(t) \leq s_i(t')$  and  $r_i(t) \leq r_i(t')$ . This follows from the definition.
- 2. The total number of messages sent or received is monotonic, that is,  $t \le t'$  implies  $S(t) \le S(t')$  and  $R(t) \le R(t')$ .
- 3.  $R^* \le R(t_2)$ . This follows from (1) and the fact that all values  $r_i$  are collected before  $t_2$ .

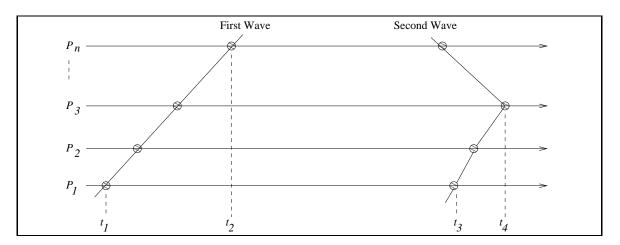

Figure 7.10: An example showing two control waves.

- 4. S'\* $\geq$  S( $t_3$ ). This follows from (1) and the fact that all values  $s_i$  are collected after  $t_3$ .
- 5. For all  $t: R(t) \le S(t)$ . This is because the number of messages in transit  $D(t) := S(t) R(t) \ge 0$ .

Now we show that if  $R^* = S^{**}$ , then the computation had terminated at the end of the first wave.

$$R* = S' * : R(t_2) \ge S(t_3)$$
$$: R(t_2) \ge S(t_2)$$
$$: R(t_2) = S(t_2)$$

That is, the computation terminated at t2 (at the end of the first wave).

If the system terminated before the start of the first wave, it is trivial that all messages arrived before the start of the first wave, and hence the values of the accumulated counters will be identical. Therefore, termination is detected by the algorithm in two "rounds" after it had occurred. Note that the second wave of an unsuccessful termination test can be used as the first wave of the next termination test. However, a problem with this method is to decide when to start the next wave after an unsuccessful test - there is a danger of an unbounded control loop.

## 7.8.4 The Sceptic Algorithm

Note that the values of the counters obtained by the first wave of the four counter method can become corrupted if there is some activity at the right of the wave. To detect such activity, we use *flags* which are initialized by the first wave, and set by the processes when they receive (or alternatively when they send) messages. The second wave checks if any of the flags have been set, in which case a possible corruption is indicated. A general drawback is that at least two waves are necessary to detect the termination.

It is possible to devise several variants based on the *logical control topology*. If the initiator asks every process individually, it corresponds to a star topology. It is possible to implement the sceptic algorithm on a ring, however, symmetry is not easily achieved since different waves may interfere when single flag is used at each process. Spanning tree is also an interesting control configuration.

Echo algorithms used as a parallel graph traversal method induce two phases. The "down" phase is characterized by the receipt of a first control message which is propagated to all other neighbors, and the "up" phase by the receipt of the last of the echoes from its neighboring nodes. These two phases can be used as two necessary waves of the sceptice method for termination detection.

#### 7.8.5 The Time Algorithm

The time algorithm is a single wave detection algorithm where termination can be detected in one single wave after its occurrence at the expense of increased amount of control information or augmenting every message with a timestamp. In the time algorithm, each process has a *local clock* represented by a counter initialized to 0.

A control wave started by the initiator at time i, accumulates the values of the counters and "synchronizes" the local clocks by setting them to i+1. Thus, the control wave separates "past" from "future". If a process receives a message whose *timestamp* is greater than its own local time, the process has received a message from the future (i.e., the message crossed the wave from right to left) and the message has corrupted the counters. After such a message has been received, the current control wave is nullified on arrival at the process.

#### **Formal Description**

Every process  $P_j$  ( $1 \le j \le n$ ) has a local message counter COUNT (initialized to 0) that holds the value  $s_j$  -  $r_j$ , a local discrete CLOCK (initialized to 0), and a variable TMAX (also initialized to 0) that holds the latest send time of all messages received by  $P_j$ .

The psuedo code for process  $P_j$  is as follows:

```
(a) When sending a basic message to P_i:
1.
          COUNT \leftarrowCOUNT +1;
2.
          send <CLOCK,...> to P_i;
        /* time-stamped basic message */
(b) When receiving a basic message <TSTAMP,...>:
3.
          COUNT←COUNT -1;
4.
          TMAX←max(TSTAMP, TMAX);
          /* process the message */
5.
(c) When receiving a control message <TIME, ACCU, INVALID, INIT>:
          CLOCK← max(TIME, CLOCK): /* synchronize the local closk */
6.
7.
          if INIT = i /* complete round? */
8.
               then if ACCU = 0 and not INVALID
9.
                      then "terminated" else "try again";
10.
                      endif:
11.
                 else send <TIME, ACCU + COUNT, INVALID or TMAX>TIME, INIT>
```

```
to P_{(i \mod n)+1};
```

12. **end if**;

```
(d) When starting a control round:
```

- 13. CLOCK←CLOCK +1;
- 14. **send** <CLOCK, COUNT, false, j > to  $P_{(j \mod n)+1}$ ;

A control message consists of four parameters, the (local) time at which the control round was started, the accumulator for the message counters, a flag which is set when a process has received a basic message from future (TMAX>TIME) and the identification of the initiating process. The first component of a basic message is always the timestamp.

For each single control wave, any basic message that crosses the wave from the right side of its induced cut to its left side is detected. Note that different control waves do not interfere; they merely advance the local clocks further. Once the system is terminated, the values of the TMAX variables remain fixed and since for every process  $P_j$ ,  $TMAX_j \le \max CLOCK_i$   $(1 \le i \le n)$ , the process with the maximum clock value can detect global termination in one round. Other processes may need more rounds.

#### 7.8.6 Vector Counters Method

Vector counters method of termination detection consists of counting messages in such a way, that it is not possible to mislead the accumulated counters.

The configuration used is the ring with n processes where every process  $P_j$  ( $1 \le j \le n$ ) has a COUNT vector of length n, where COUNT[i] ( $1 \le i \le n$ ) denotes the i-th component of the vector. A circulating control message also consists of a vector of length n. For each process  $P_j$ , the local variable COUNT[i] ( $i \ne j$ ) holds the number of basic messages which have been sent to process  $P_i$  since the last visit of the control message. Likewise, the negative value of COUNT[j] indicates how many messages have been received from any other process. At any (global) time instant, the sum of the k-th components of all n COUNT vectors including the circulating control vector equals the number of messages currently on their way to process  $P_k$ ,  $1 \le k \le n$ . This property is maintained invariant by the implementation given below. For simplicity, we assume that no process communicates with itself,  $P_{n+1}$  is identical to  $P_1$ , an operation on a vector is defined by the operating on each of its components, and 0\* denotes the null vector.

The psuedo code for process  $P_j$  is as follows:

COUNT is initialized to 0\*

- (a) When sending a basic message to  $P_i$   $(i \neq j)$ :
- 1.  $COUNT[i] \leftarrow COUNT[i]+1;$
- (b) The following instructions are executed at the end of all local actions triggered by the receipt of a basic message:

```
2.
          COUNT[j] \leftarrow COUNT[j]-1;
3.
          if COUNT[j] = 0 then
4.
                  if COUNT = 0*
                           then "system terminated"
                           \textbf{else send} \ \text{accumulate} < \! \text{COUNT} \! \! > \text{to} \ P_{j+1};
5.
6.
                           COUNT←0*;
7.
                  end if;
8.
          end_if;
(c) When receiving a control message 'accumulate < ACCU>':
9.
          COUNT←COUNT + ACCU;
10.
           if COUNT [j] < 0 then
11.
                   if COUNT = 0*
                          then "system terminated"
12.
                          else send accumulate <COUNT> to P_{j+1};
13.
                          COUNT\leftarrow 0*;
                   end_if;
14.
15.
           end if;
```

An initiator  $P_i$  starts the algorithm by sending the control message 'accumulate <0\*>' to  $P_{i+1}$ . A mechanism is needed to ensure that every process is visited at least once by the control message, i.e., that the control vector makes at least one complete round after the start of the algorithm.

Every process counts the number of outgoing messages individually by incrementing the counter indexed by the receiver's process number (line 1); the counter indexed by its own number is decremented on receipt of a message (line 2). When a process receives the circulating control message, it accumulates the values in the message to its COUNT vector (line 9). A check is then made (line 10) to determine whether any basic messages known to the control message have still not arrived at  $P_j$ . If this is the case (COUNT[j]>0), the control message is removed from the ring and regenerated at later time (line 5) when all expected messages have been received by  $P_j$ . For this purpose, every time a basic message is received by a process  $P_j$ , a test is made to check whether COUNT[j] is equal to 0 (line 3). Note that lines 4-15 are only executed when the control vector is at  $P_j$ . Note that there is at most one process  $P_j$  with COUNT[j]>0, and if this is the case at  $P_j$ , the control vector "waits" at process  $P_j$  (lines 11 to 13 are not executed and the control vector remains at  $P_j$ ).

If it is not required that the control message waits at nodes for outstanding basic messages, the algorithm can be simplified considerably by removing lines 3-8 as well as lines 10 and 15.

#### **Performance**

The number of control messages exchanged by this algorithm is bounded by n(m+1), m denotes the number of basic messages, because at least one basic message is received in every round of the control message, excluding the first round. Therefore, the worst case communication complexity for this algorithm is O(mn).

#### 7.8.7 A Channel Counting Method

The channel counting method is a refinement of the vector counter method in the following way: a process keeps track of the number of messages sent to each process and keeps track of the number of messages received from each process, using appropriate counters.

Each process  $P_j$  has n counters,  $C_{j1}^+,...,C_{jn}^+$ , for outgoing messages and n counters,  $C_{1j}^-,...,C_{nj}^-$ , for incoming messages.  $C_{ij}^-$  is incremented when  $P_j$  receives a message from process  $P_i$ , and  $C_{jk}^+$  is incremented when  $P_j$  sends a message to  $P_k$ . Upon demand, each process informs the values of the counters to the initiator. The initiator reports termination if  $C_{ij}^- = C_{ij}^+$  for all i,j.

The method becomes more practical if it is combined with the echo algorithm, where test messages flow down on every edge of the graph and echoes proceed in the opposite direction. The value of  $C_{ij}^-$  is transmitted upwards from process  $P_j$  to  $P_i$  in an echo; whereas, a test message sent by  $P_i$  to  $P_j$  carries the value of  $C_{ij}^+$  with it. A process receiving a test message from another process (the activator), propagates it in parallel to any other process to which it sent basic messages whose receipts have not yet been confirmed. If it has already done this, or if all basic messages sent out have been confirmed, an echo is immediately sent to the activator. There are no special acknowledgement messages. A process  $P_i$  receiving the value of  $C_{ij}^-$  in an echo, knows that all messages it sent to  $P_j$  have arrived if the value of  $C_{ij}^-$  equals the value of its own counter  $C_{ij}^+$ . An echo is only propagated towards the activator if an echo has been received from each subtree and all channels in the subtrees are empty.

## **Formal Description**

Each process  $P_i$  has the following arrays of counters:

- 1. OUT[i]: counts the number of basic messages sent to  $P_i$ .
- 2. IN[i]: counts the number of basic messages received from  $P_i$ .
- 3. REC[i]: records the number of its messages  $P_i$  is aware have been received by  $P_i$ .

OUT[i] corresponds to  $C_{ji}^+$  and IN[i] to  $C_{ij}^-$ . A variable ACTIVATOR is used to hold the index number of the activating process and a counter DEGREE indicates how many echoes are still missing.

The psuedo code for process  $P_j$  is as follows:

```
{OUT, IN, REC are initialized to 0* and DEGREE to 0.}
(a) When sending a basic message to P_i:
          OUT[i] \rightarrow OUT[i]+1;
1.
(b) When receiving a basic message from P_i:
2.
          IN[i] \leftarrow IN[i] + 1;
(c) On the receipt of a control message test < m > from P_i where m <IN[i]:
          if DEGREE > 0 or OUT = REC /* already engaged or subtree is quiet */
3.
4.
                 then send echo \langle IN[i] \rangle to P_i;
5.
                 else ACTIVATOR\leftarrow i; /* trace activating process */
6.
                 PROPOGATE /* and test all subtrees */
7.
          end_if;
(d) On the receipt of a control message echo < m > from P_i:
8.
          REC[i] \leftarrow m;
9.
          DEGREE←DEGREE - 1; /* decrease missing echoes counter */
10.
           if DEGREE=0 then
/* last echo checks whether all subtrees are quiet */
11.
                   PROPAGATE;
12.
           end if;
13.
           if DEGREE=0 then /*all echoes arrived, everything quiet */
14.
                   send echo \langle IN[ACTIVATOR] \rangle to P_{ACTIVATOR};
15.
           end if:
(e) The procedure PROPAGATE called at lines 6 to 11 is defined as follows:
16. procedure PROPAGATE:
17.
           loop for K = 1 to n do
18.
                   if OUT[K]≠REC[K] then /* confirmation missing */
```

Varibale DEGREE is incremented when a process sends a test message (line 20) and it is decremented when a process receives an ECHO message (line 9). If DEGREE >0, it means the node is "engaged" and a test message is immediately responded to with an echo message (line 4). An echo is also returned for a test message if OUT = REC (line 3), i.e., if process sent no messages at all

send test <OUT[K]> to  $P_k$ ; /\* check subtree \*/

DEGREE←DEGREE + 1;

end\_if;

end\_loop;

23. end\_procedure;

19.20.

21.

22.

or if all messages sent out by it have been acknowledged. Lines 10-15 insure that an echo is only returned if the arrival of all basic messages has been confirmed and all computations in the subtree finished. This is done by sending further test messages (via procedure PROPAGATE) after the last echo has arrived (lines 10-12). These test messages visit any of the subtree root processes which have not yet acknowledged all basic messages sent to them. The procedure PROPAGATE increases the value of the variable DEGREE if any processes are visited, thus preventing the generation of an echo (lines 13-15).

To minimize the number of control messages, test messages should not overtake basic messages. To achieve this, test messages carry with them a count of the number of basic messages sent over the communication channel (line 19). If a test messages overtakes some basic messages (and it is not overtaken by basic messages), its count will be greater than the value of the IN-counter of the receiver process. In this case, the test message is put on hold and delivered later when all basic messages with lower count have been received (guard  $m \leq IN[i]$  in point(c) insures this).

The initiator starts the termination test only once, as if it had received a test < 0 > message from some imaginary process  $P_0$ . On termination detection, instead of eventually sending an echo to  $P_0$ , it reports termination. Test messages only travel along channels which were used by basic messages; processes that did not participate in the distributed computation are not visited by test messages. For each test message, an echo is eventually sent in the opposite direction.

#### **Performance**

At least one basic message must have been sent between the send of two test messages along the same channel. This results in an upper bound of 2m control messages, where m denotes the number of basic messages. Hence, the worst case communication complexity is O(m). However, The worst case should rarely occur, specially, if the termination test is started well after the computation started. In many situations, the number of control messages should be much smaller than m. The exact number of control messages involved in channel counting is difficult to estimate because it is highly dependent on communication patterns of the underlying computation.

## 7.9 Termination Detection in a Faulty Distributed System

An algorithm is presented that detects termination in distributed systems in which processes fail in a fail-stop manner. The algorithm is based on the weight-throwing method. In such a distributed system, a computation is said to be terminated if and only if each healthy process is idle and there is no basic message in transit whose destination is a healthy process. This is independent of faulty processes and undeliverable messages (i.e., whose destination is a faulty process). Based on the weight-throwing scheme, a scheme called flow detecting scheme is developed by Tseng [20]to derive a fault-tolerant termination detection algorithm.

#### **Assumptions**

Let  $S = P_1$ ,  $P_2$ , ...,  $P_n$  be the set of processes in the distributed computation.  $C_{ij}$  represents the bidirectional channel between  $P_i$  and  $P_j$ . Communication network is asynchronous. Communications channels are reliable, but they are non-FIFO. At any time, an arbitrary number of processes may fail. However, the network remains connected in the presence of faults. Fail-stop model implies that a failed process stops all activities and can not rejoin the computation in the current session. Detection of faults takes a finite amount of time.

#### 7.9.1 Flow Detecting Scheme

Weights may be lost because a process holding non-zero weight may crash or a message destined to a crashed process is carrying a weight. Thus, due to faulty processes and undeliverable messages carrying weights, it may not be possible for the leader to accumulate the total weight of 1 to declare termination. Thus, in case of a process crash, the lost weight must be calculated. To solve this problem, concept of flow invariant is used.

#### The Concept of Flow Invariant

Define  $H \subseteq S$  the set of all healthy processes. Define *subsystem* H to be part of the system containing all processes in H and communication channels connecting two processes in H. According to the concept of flow invariant, weight change of the subsystem during the time interval I, during which the system is doing computation, is equal to (weights flowing into H during I) — (weights flowing out of H during I). To implement this concept, a variable called  $\operatorname{net}_i$  is assigned to each process  $P_i$  belonging to H. This variable records the total weight flowing into and out of the subsystem H. Initially,  $\forall i$   $\operatorname{net}_i = 0$ . The following flow-detecting rules are defined.

**Rule 1:** Whenever a process  $P_i$  which belongs to H receives a message with weight x from another process  $P_j$  which does not belong to H, x is added to  $\text{net}_i$ .

**Rule 2:** Whenever a process  $P_i$  which belongs to H sends a message with weight x to a process  $P_j$  which does not belong to H, x is subtracted from  $net_i$ .

Let  $W_H$  be the sum of the weights of all processes in H and all in-transit messages transmitted between processes in H.

$$W_H = \sum_{P_i \in H} (\text{net}_i + 1/n)$$

where, 1/n is the initial weight held by each process  $P_i$ .

Let  $\overline{H} = S - H$  be the set of faulty processes. The distribution of weights is divided into four

parts:

 $W_H$ : weights of processes in H.

 $W_{\overline{H}}$ : weights of processes in  $\overline{H}$ .

 $W_{H \to \overline{H}}$ : weights held by in-transit messages from H to  $\overline{H}$ .

 $W_{\overline{H}\to H}$ : weights held by in-transit messages from  $\overline{H}$  to H.

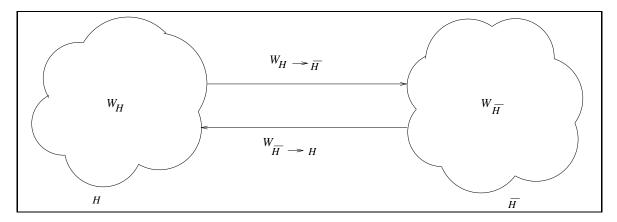

Figure 7.11: Healthy and faulty process sets and message flow between them.

This is shown in Figure 7.11.  $W_{\overline{H}}$  and  $W_{H\to \overline{H}}$  are lost and can not be used in the termination detection.

## **7.9.2** Taking Snapshots

In distributed systems, due to the lack of a perfectly synchronized global clock, it is not possible to get a global view of the subsystem H and hence it may not possible to determine  $W_H$ . We obtain  $\overline{W}_H$ , which is an estimated value of  $W_H$  by taking snapshots on the subsystem H and by using the above equation for  $W_H$ .

However, note that weights in  $W_{\overline{H}\to H}$  carried by in-transit messages may join H and change  $W_H$ . To obtain a stable value of  $W_H$ , channels from  $\overline{H}$  to H are disconnected before taking snapshots of H. Once a channel is disconnected, a healthy process can no longer send or receive messages along this channel.

A snapshot on H is the collection of  $\operatorname{net}_i$ 's from all processes in H. A snapshot is said to be consistent if all channels from H to  $\overline{H}$  are disconnected before taking the snapshot (i.e., recording the values of  $\operatorname{net}_i$ ).

A snapshot is taken upon a snapshot request by the leader process. The leader uses the information in a consistent snapshot and equation to compute  $W_H$  to calculate  $\overline{W}_H$ . Snapshots are requested when a new faulty process is found or when a new leader is elected. It should be noted that  $\overline{W}_H$  is an estimate of the weight that is remaining in the system. This is because processes can fail and stop any time and there may not exist any point in real time in the computation where H is the healthy set of processes. Suppose H' is the set of healthy processes at some point in time in the computation after taking the snapshot. If H = H', then  $\overline{W}_H = W_{H'}$ ; otherwise,  $\overline{W}_H \geq W_{H'}$  must

be true, because of the fail stop model of processes. This eliminates the possibility of declaring termination falsely. Thus, the leader can safely declare termination after it has collected  $\overline{W}_H$  of weight.

### 7.9.3 Description of the Algorithm

The algorithm combines the weight-throwing scheme, the flow detecting scheme and a snapshot-recording scheme. Process  $P_i$  elects itself the leader if it knows that all  $P_j$ , j < i, are faulty. The leader process takes snapshots and estimates remaining weight in the system.

#### **Data Structures**

The following data structures are used at process a  $P_i$ , i=1, ...,n:

- $l_i$  is the id of the leader known to  $P_i$ . Initially  $l_i=1$
- $w_i$  is the weight currently held by  $P_i$ . Initially  $w_i = 1/n$ .
- $s_i$  is the systems total weight assumed by  $P_i$ .  $P_i$  will try to collect this amount of weight. Initially,  $s_i=1$ .
- NET<sub>i</sub>[1,...,n] is an array real numbers. NET<sub>i</sub>[j] keeps track of the total weight flowing into  $P_i$  from  $P_j$ . Initially, NET<sub>i</sub>[j]=0 for all j=1,...,n.
- $F_i$  is a set of faulty processes. A process  $P_j$  belongs to  $F_i$  if and only if  $P_i$  knows that  $P_j$  is faulty and  $P_i$  has disconnected its channel to  $P_i$ . Initially,  $F_i$  is a null set.
- $SN_i$  is a set of processes. When  $P_i$  initiates a snapshot,  $SN_i$  is a set of processes to which  $P_i$  sends snapshot requests. A process  $P_j$  belonging to  $SN_i$  is removed from  $SN_i$  if  $P_i$  receives a reply from  $P_j$  or if  $P_i$  finds  $P_j$  is faulty. No new snapshot is started unless  $SN_i$  is an empty set. Initially,  $SN_i$  is a null set, which implies no snapshot is in progress.
- t<sub>i</sub> is used for temporarily calculating the total remaining weight while a snapshot is in progress.
- $\bullet$  c<sub>i</sub> a boolean, used for temporarily calculating the consistency of a snapshot.

#### **Types of Messages**

The following four types of messages are exchanged by the algorithm:

- B(x) is a basic message B with weight x.
- C(x) is a control message that is used to report weight x to the leader process.

- Request( $F_i$ ) is a snapshot requesting message sent by the leader process  $P_i$ . The set  $F_i$  is to inform the receiver the set of faulty processes known to  $P_i$ .
- Reply( $F_j$ , NET<sub>j</sub>) is the state reporting message sent by  $P_j$  in reply to the leader's Request() message.

#### The Algorithm

The algorithm is described for process  $P_i$ . The algorithm consists of nine event-driven atomic actions, each having the format "(guard)  $\rightarrow$  (actions)". Actions are triggered by sending/receiving messages, changing local states, or detecting new faulty processes. The following actions from A1 to A5 implement weight throwing and flow detecting schemes.

```
A1: (P_i \text{ sending a basic message B to } P_i) \rightarrow
          w_i is partitioned into x and y such that x>0, y>0 and x+y=w_i;
          B(x) is sent to P_i;
         NET_i[j] := NET_i[j] - x;
          \mathbf{w}_i := y;
A2: (P_i \text{ receiving a basic message } B(x) \text{ from } P_i) \rightarrow
          NET_i[j] := NET_i[j] + x;
          \mathbf{w}_i := \mathbf{w}_i + x;
          pass the basic message to the underlying system;
A3: (P_i becoming idle) \rightarrow
          if l_i \neq i then
                    send C(w_i) to P_{l_i};
                    NET_i[l_i] := NET_i[l_i] - w_i;
                    w_i := 0;
          end if;
A4: (P_i \text{ receiving a control message } C(x) \text{ from } P_j) \rightarrow
          NET_i[j] := NET_i[j] + x;
          \mathbf{w}_i := \mathbf{w}_i + x;
A5: (P_i \text{ is idle}) \land (s_i = w_i) \rightarrow
          announce "termination";
```

A1 is activated when  $P_i$  sends a basic message to another process. A2 is triggered by receiving a basic message. A3 is the weight reporting action. When  $P_i$  is not the leader, it sends its weight to the leader process in a control message. A4 describes  $P_i$ 's response on receiving a con-

trol message. In all actions A1-A4,  $NET_i[1...n]$  records the weight flowing information. In A5, leader  $P_i$  announces the termination.

The following actions from F1 to F4 deal with faults and take snapshots of the system.

```
(* Actions for detecting a fault when no snapshot is in progress *)
F1: (P_i \text{ detecting } P_i \text{ faulty}) \land (P_i \not\in F_i) \land (SN_i = \emptyset) \rightarrow
           disconnect the channel from P_i to P_j;
            F_i := F_i \cup \{P_i\};
            l_i = \min\{k \mid P_k \in S - F_i\};
            if (l_i = i), then call snapshot(); end if;
(* Actions on receiving a snapshot request *)
F2: (P_i \text{ receiving Request}(F_i) \text{ from } P_i) \rightarrow
            l_i := j;
           for every P_f belonging to F_j - F_i, disconnect the channel C_{i,f};
            F_i := F_i \cup F_i;
            Send a Reply(F_i, NET<sub>i</sub>[1...n]) to P_i;
(* Actions on receiving a snapshot response *)
F3: (P_i \text{ receiving Reply}(F_i, \text{NET}_i[1...n] \text{ from } P_i) \rightarrow
            if (F_i \neq F_i) \vee \neg c_i then
                   for every P_f belonging to F_i - F_i, disconnect the channel C_{i,f};
                   F_i = F_i \cup F_i;
                   c_i = false;
            else
                   t_i = t_i + 1/n + \sum_{P_f \in F_i} \text{NET}_j[f];
            end if:
            SN_i = SN_i - \{P_i\};
            if SN_i = \emptyset then
                   if c_i then s_i := t_i else call snapshot(); end if;
            end if;
(* Actions for detecting a fault when a snapshot is in progress *)
F4: (P_i \text{ detecting } P_j \text{ faulty}) \land (SN_i \neq \emptyset) \rightarrow
            Disconnect the channel C_{i,j};
            F_i := F_i \cup \{P_i\};
            c_i:= false;
           SN_i := SN_i - \{P_i\};
            if SN_i = \emptyset then call snapshot(); end if;
```

```
(* Snapshot taking procedure *) 

Procedure snapshot() (* assuming the caller is P_i *) 

Begin SN_i = S - F_i - \{P_i\}; \text{ (* processes that will receive requests *)} 
\forall P_k \in SN_i, \text{ send a Request}(F_i) \text{ to } P_k; 
t_i := 1/n + \sum_{P_f \in F_i} \text{NET}_i[f]; 
c_i := \text{true}; 
end;
```

F1 is triggered when  $P_i$  detects for the first time that a process  $P_j$  is faulty and no snapshot is currently in progress. The channel from  $P_i$  to  $P_j$  is disconnected. Then  $P_i$  elects a healthy process with least id as its leader. If process  $P_i$  itself is the leader, then it invokes snapshot procedure to initiate a snapshot.

In the snapshot() procedure, first  $SN_i$  is set to the set of processes to which Request()'s are to be sent and sends a Request() to these processes. This prevents F1 from being executed until the snapshot finishes. Assuming that the current healthy process set is  $S - F_i$  and this snapshot is consistent, more weight is added to  $t_i$  as  $P_i$  receives Reply() messages from other processes.

F2 describes  $P_i$ 's response on receiving a Request() message from  $P_j$ .  $P_i$  disconnects channels to faulty processes and sends a Reply() message to  $P_j$ , that sent the Request() message.

The initiator of the snapshot  $P_i$  waits for each  $P_j$  belonging to  $SN_i$  for either a Reply() coming from  $P_j$  or  $P_j$  being detected as faulty.

If a Reply() is received from  $P_j$ , F3 is executed. F3 describes  $P_i$ 's actions on receiving such a snapshot response. The consistency of the snapshot is checked. If the snapshot is still consistent,  $t_i$  is updated. Then the barrier  $SN_i$  is reduced by one. If the barrier becomes null and the snapshot is consistent,  $s_i$  is updated to  $t_i$ . If the snapshot is not consistent, another snapshot is initiated.

The snapshot initiator  $P_i$  executes F4 when it detects a process  $P_j \in SN_i$ , is faulty and a snapshot is in progress. Another snapshot is started only when  $SN_i=\emptyset$ . Such a procedure is repeated until a consistent snapshot is obtained. Because of the fail stop model of processes, the number of healthy processes is a non-increasing function of time and eventually the procedure will terminate.

## 7.9.4 Performance Analysis

If k processes become faulty, at most 2k snapshots will be taken. Each snapshot costs at most n-1 Request()s and n-1 Reply()s. Thus, the message overhead due to snapshots is bounded by 4kn.

If M basic messages are issued, processes will be activated by at most M times. So processes will not turn idle more than M + n times. So at most M + n control messages C(x) will be issued. Thus, the message complexity of the algorithm is O(M + kn + n).

The termination detection delay is bounded by O(k+1). The termination detection delay is defined as the maximum number of message hops needed, after the remination has occurred, by the algorithm to detect the termination.

## 7.10 Bibliographic Notes

The termination detection problem was brought to prominence in 1980 by Francez [5] and by Dijkstra and Scholten [4]. Since then, a large number of termination detection algorithms having different features and for a variety of logical system configurations have been developed. A termination detection algorithm that uses distributed snapshot is discussed in [8]. A termination detection algorithm based on weight throwing is discussed in [9]. A termination detection algorithm based on weight throwing was first developed by Mattern [13]. Dijkstra et al. [3] present a ring-based termination detection algorithm. Topor [19] adapts this algorithm to a spanning tree configuration. Chandrasekaran and Venkatesan [2] present a message optimal termination detection algorithm. Brzezinski et al. [1] define a very general model of the termination problem, introduce the concept of static and dynamic terminations, and develop algorithms to detect static and dynamic terminations. Mattern developed [12] several algorithms for termination detection for the atomic model of computation. An algorithm for termination detection under faulty processes is given by Tseng [20]. Mayo and Kearns [14, 15] present efficient termination detection based on roughly synchronized clocks. Other algorithms for termination detection can be found in [6, 10, 11, 16, 17, 18, 21].

Many termination detection algorithms use a spanning tree configuration. An efficient distributed algorithm to construct a minimum weight spanning tree is given in [7].

## 7.11 Exercise Problems

- 1. Haung's termination detection algorithm could be redesigned using a counter to avoid the need of splitting weights. Present an algorithm for termination detection that uses counters instead of weights.
- 2. Design a termination detection algorithm that is based on the concept of weight throwing and is tolerant to message losses. Assume that processe do not crash.
- 3. Termination detection algorithms assume that an idle process can only be activated on the reception of a message. Consider a system where an idle process can become active spontaneously without receiving a message. Do you think a termination detection algorithm can be designed for such a system? Give reasons for your answer.

- 4. Design an efficient termination detection algorithm for a system where communication delay is zero.
- 5. Design an efficient termination detection algorithm for a system where computation at a process is instantaneous (that is, all process are always in the idle state.)
